**AETOSAURUS** (ARCHOSAUROMORPHA) FROM THE UPPER TRIASSIC OF THE NEWARK SUPERGROUP, EASTERN UNITED STATES, AND ITS BIOCHRONOLOGICAL SIGNIFICANCE

by SPENCER G. LUCAS, ANDREW B. HECKERT and PHILLIP HUBER

**ABSTRACT.** Four specimens of the aetosaur *Stegomus* are known from Upper Triassic strata of the Newark Supergroup of the eastern United States. These specimens represent a small aetosaur with a long narrow carapace that is distinctly waisted in front of the hindlimbs, has paramedian scutes much wider than long and lateral scutes that lack spikes. *Stegomus* is thus remarkably similar to *Aetosaurus* Fraas, but has weaker sculpturing on its scutes. This is the principal difference between the two, so we regard *Stegomus* as a junior subjective synonym of *Aetosaurus* and recognize a distinct Newark species, *Aetosaurus arcticus* (Marsh).

*Aetosaurus* in the Newark Supergroup is of biochronological significance because the genus has a broad distribution and one of its occurrences can be directly cross-correlated to Triassic marine biochronology. *Aetosaurus* is of early-mid Norian age in the German Lower and Middle Stubbensandstein. *Aetosaurus* has been found in mid Norian marine limestones in Italy correlated to the *Himavatites columbianus* ammonite Zone, which directly cross-correlates the genus to the standard global chronostratigraphical scale. *Aetosaurus* is present in the Bull Canyon Formation (Chinle Group) of eastern New Mexico, USA and in the Ørsted Dal Member of the Fleming Fjord Formation in Greenland; both of these units are of early Norian age. *Aetosaurus* localities in the Newark Supergroup are of mid Norian age, a conclusion consistent with Newark palynostratigraphy and magnetostratigraphy. *Aetosaurus* is thus an index fossil of the lower-middle Norian.

**AETOSAURS** were herbivorous archosaurs of the Late Triassic. Their heads are extremely small relative to their bodies, their rostra lack teeth, and they have small, leaf-shaped maxillary and dentary teeth. The heavily armoured body has quadrangular plates that run form the back of the skull to the tip of the tail and encase much of the abdomen as well as the entire tail. The tarsus is crocodile normal, and the ichnogenus *Brachychirotherium* probably represents aetosaur footprints (Lockley and Hunt 1995).

Aetosaur fossils have a broad geographical distribution (Text-fig. 1) and are among the most common tetrapod fossils in many Late Triassic, non-marine strata. Distribution, abundance, and ease of identification make aetosaurs useful Late Triassic non-marine index fossils (Lucas and Heckert 1996; Hecker et al. 1996).

Here, we re-evaluate the taxonomy of one of the first aetosaurs described from North America, *Stegomus arcticus* Marsh, 1896. We conclude that *Stegomus* is a junior subjective synonym of the European aetosaur genus *Aetosaurus* Fraas, 1877. This enables a robust correlation of *Aetosaurus* localities in the United States, Greenland, Germany and Italy, and thus further develops the biochronological utility of aetosaurs.

**Institutional abbreviations.** NCSM, North Carolina State Museum, Raleigh, North Carolina, USA; NJSNM, New Jersey State Museum, Trenton, New Jersey, USA; NMMNH, New Mexico Museum of Natural History and Science, Albuquerque, New Mexico, USA; PU, Princeton University collection, now at Yale Peabody Museum; SMNS, Staatliches Museum für Naturkunde, Stuttgart, Germany; YPM, Yale Peabody Museum, New Haven, Connecticut, USA.

TEXT-FIG. 1. Map of Late Triassic Pangaea showing aetosaur localities and highlighting Aetosaurus records, which are: 1 = Newark Supergroup, eastern North America; 2 = Chinle Group, western United States; 3 = Fleming Fjord Formation, Greenland; 4 = Keuper Triassic, Germany; 5 = Alpine marine Triassic, Lombardian Alps, Italy.

* Measurement of incompletely exposed or preserved scute.
TEXT-Fig. 2. Aetosaurus arcuatus (Marsh, 1896); YPM [PU] 21759, skull and anterior portion of neck. Abbreviations: af = antorbital fenestra; c = cervical paramedian scutes; f = frontal; m = maxilla; n = nuchal scutes; na = nasals; o = orbit; p = parietal; pf = prefrontal; pm = premaxilla; po = postorbital; sq = squamosal; t = temporal fenestra. Skull drawing modified from Baird (1986); ×1.1.

Material. YPM [PU] 21750, natural cast of ventral aspect of skull and dorsal carapace (Baird 1986, figs 12, 14a; Pl. 2; Text-fig. 2); from the Passaic Formation on the bank of Nishisakawick Creek, Huntendon County, New Jersey.

NJSM 10740, partial tail (Jepsen 1948, pls 1–2; Baird 1986, fig. 13; Text-fig. 3a); from the Passaic Formation near Neshanic Station in Somerset County, New Jersey.

NCSM 11756 partial tail (Huber et al. 1993a, fig. 5) (Text-fig. 4A–B); from ‘Lithofacies Association II’ (= Lower Sanford Formation) at the Triangle Brick Quarry, North Carolina.

Revised diagnosis. A species of Aetosaurus distinguished from A. ferratus Fraas, 1877 and A. crassicauda Fraas, 1907 by the relatively large (3.5:1) width : length ratio of the dorsal paramedian scutes in adult specimens, very faint pitting on the scutes, and a tail that narrows rapidly posteriorly.

Description. Marsh (1896) and Lull (1915, 1953) described the holotype of Stegomas arcuatus, and Jepsen (1948) and Baird (1986) described the New Jersey specimens. Parker (1966) described the partial tail from North Carolina, and this specimen was later illustrated by Huber et al. (1993a, fig. 5).
The holotype, YPM 1647, consists of the natural mould of the median portion of a carcass that preserves 16 articulated rows of paramedian and lateral scutes and apparently was rolled and contracted dorsally before burial (pl. 1). The specimen is preserved as a natural sandstone mould of the ventral surface of the dorsal armour and also includes seven matrix blocks that include portions of the mould. No original bone is preserved, so YPM 1647 is a steinkern preserved in red, medium- to coarse-grained, arkosic sandstone and pebbly sandstone. The total length of the preserved carapace is about 440 mm.

The so-called 'pitting' of the scutes alleged by Lull (1915, 1953) actually is porosity of the sandstone matrix, not a morphological feature. Thus, this 'pitting' can be seen both on the scute impressions and on the surrounding sandstone matrix. The carapace is composed of two columns of 16 paramedian scutes that are rectangular in shape, much wider than long (width:length c. 3:1-4:8; Table 1). Smaller, trapezoidal lateral scutes occur at the margins of all the right paramedian scutes and are attached to six of the left paramedian scutes. There is no evidence that any of the lateral scutes has spikes or protuberances. Fine details of the surface morphology of all scutes are obscured by the coarse-grained fabric of the host matrix.

Baird (1986) provided a brief, but accurate description of YPM [PU] 21750, which is the most complete specimen previously assigned to Stegomas (Pl. 2; Text-fig. 2). This is the ventral impression of the skull roof and dorsal carapace from the skull to the pelvis. It represents a small aetosaurus with a snout–pelvis length of approximately 210 mm. Skull length is about 69 mm, and width across the orbits is 17 mm. The snout tip is broken, but obviously tapered to a thin beak. The antorbital fenestra is antero-posteriorly long and dorso-ventrally short. The orbit is very large; with an antero-posterior length of 18 mm, it reaches c. 25 per cent. of skull length. This suggests that the specimen represents a juvenile (Baird 1986). Sutures for the premaxillary, maxillary, nasals, frontals, prefrontal, frontal, parietal, postorbital and squamosal are present, and are as Baird (1986, fig. 14A) indicated (Text-fig. 2).

A scute covers the occiput and is followed by two columns of 21 pairs of paramedian scutes. These scutes are rectangular—much wider than long (width:length ~ 3:1-4:0; Table 1)—and imbricated. The posterior edge of each scute overlaps (is dorsal to) the anterior edge of the scute behind it. This scute morphology is best illustrated by the natural cast of the scutes that infilled the posterior portion of the mould (Pl. 2, fig. 2). Scute morphology is strikingly similar to that of YPM 1647, although the New Jersey specimen is significantly smaller. The carapace of the New Jersey specimen narrows noticeably toward the pelvis.

NJSM 10740 is part of the dorsal portion of a tail (Text-fig. 3b). Jepsen (1948) provided an accurate description, and we only draw attention to a few key features. Note that the dorsal paramedian scutes are rectangular and wider than long (width:length ~ 1:6-1:7; Table 1). They are imbricated: the posterior edge of each scute overlaps (is dorsal to) the anterior edge of the scute behind it. The lateral scutes are square to trapezoidal in shape. The tail tapers very rapidly posteriorly.

NCSM 11756 is part of a tail that preserves six rows of scutes (Text-fig. 4). Most of the bone is exfoliated from the scutes, but some preserve the original external surface of the dermal bone. These surfaces have a distinct 'sunburst' pattern of grooves and small pits that radiate away from the scute's antero-posterior axis. As in the other specimens, the paramedian scutes are rectangular and much wider than long (Table 1). The lateral scutes are square to trapezoidal. None of the scutes bear bony spikes or protuberances. The tail tapers very rapidly posteriorly.

Remarks. The four specimens of Stegomas from the Newark Supergroup characterize an aetosaurus with the following distinctive features: (1) it is relatively small in comparison to most other aetosaurs; (2) the paramedian scutes are much wider than long, with overlapping anterior bars; (3) the lateral scutes are small, trapezoidal and lack any bony spikes; (4) the paramedian scute surfaces bear a faint 'sunburst' pattern of pits and grooves; and (5) the carapace is 'waisted' (narrows, with a corresponding decrease in width:length ratios of dorsal scutes) immediately anterior to the pelvis.

**Explanation of Plate 2**

Figs 1–2. *Aetosaurus arcuatus* (Marsh, 1896); YPM [PU] 21750. 1, natural mould of ventral aspect of skull and dorsal carapace, stereophotograph; × 0:5. 2, natural cast of infilling of posterior portion of mould, stereophotograph; × 1:5.
LUCAS et al., *Aetosaurus*

Among the known aetosaurs, all these features are found only in *Aetosaurus* Fraas, 1877 (see Text-fig. 3A). Particularly significant is the pattern of pitting on the scutes and the lack of spikes or bosses. Most of the known aetosaurs have spikes on the scutes (e.g. Long and Murry 1995), but *Aetosaurus* lacks spikes and has a ‘sunburst’ pattern of pits and grooves on the scutes (e.g. Wild
TEXT-FIG. 4 *Aetosaurus arcuatus* (Marsh, 1896); NCSM 11756; North Carolina; partial tail, stereophotographs of dorsal (A) and ventral (B) aspects; ×0.66.
1989). Indeed, we are unable to distinguish specimens of Stegomas from Aetosaurus except by minor differences, so we consider the two genera to be synonymous.

On the holotype specimen of Stegomas arcutus Marsh (1896), YPM 1647 (Pl. 1; Table 1), the pattern of sculpture on the scutes cannot be determined, but the specimen still preserves numerous details consistent with its assignment to Aetosaurus. The paramedian scutes lack ventral keels and are broadly rectangular, considerably wider than long, and do not appear to have possessed thickened lateral processes for articulation of the lateral scutes, as in some other aetosaurs, such as Typothorax. The lateral scutes are slightly wider than long, flat, and lack any indication of spinescence. In these characters, YPM 1647 clearly pertains to Aetosaurus as described originally by Fraas (1877) and subsequently by Fraas (1907), von Huene (1920), Walker (1961) and Wild (1989). We retain, however, a distinct North American species of the genus, Aetosaurus arcutus (Marsh, 1896), based on the following features that distinguish it from A. ferratus Fraas, 1877 and A. crassicauda Fraas, 1907: the relatively high width:length ratio (3:5:1) of dorsal paramedian scutes in adult specimens, very faint pitting on the scutes, and rapid posterior narrowing of the tail.

DISTRIBUTION OF AETOSARUS IN THE NEWARK SUPERGROUP

Four specimens from the Newark Supergroup are referred to Aetosaurus arcutus: (1) the holotype of Stegomas arcutus Marsh from the New Haven Formation in Fair Haven, Connecticut; (2) the holotype of S. arcutus jersenensis Jepsen, an incomplete tail from the lower Passaic Formation at Neshanic Station, New Jersey; (3) the natural mould of the skull and dorsal armour of a juvenile from the Passaic Formation, Nishisakawick Creek, New Jersey; and (4) a partial tail from the 'Sanford Formation' at Triangle Brick Quarry, North Carolina.

The holotype of Aetosaurus arcutus (Marsh, 1896) was collected by Freeman P. Clark in his brownstone quarry at Fair Haven, located within the city limits of New Haven, Connecticut. This quarry is developed in the New Haven Formation, a red-bed unit that consists mostly of arkosic sandstone and conglomeratic sandstone. The lower part of the New Haven Formation has yielded a Carnian–Norian palynoflora (Cornet 1977), and the upper part the procolophonid Hypsognathus and a sphenodontid (cf. Sigmsala) indicative of a latest Triassic (probably Rhaetian) age (Huber et al. 1993b; Lucas and Huber 1993). The Aetosaurus arcutus holotype is from the middle part of the New Haven Formation, which has been assigned a mid Norian age based on correlation with other, better dated Newark Supergroup strata (Lucas and Huber 1993).

The New Jersey specimens of Aetosaurus were both obtained from the Passaic Formation. The specimen described by Jepsen (1948) was recovered from a cellular excavation in strata belonging to the Neshanic Member of the Passaic Formation at Neshanic Station, New Jersey. The specimen described by Baird (1986) was obtained as a loose boulder from the bed of Nishisakawick Creek in nearby Frenchtown, New Jersey, from the stratigraphically lower Warwick Member of the Passaic Formation. In the Newark basin, the thickness of the stratigraphical interval from the Warwick to the Neshanic members of the Passaic Formation is about 600 m (Olsen et al. 1996, fig. 8). Based on palynostratigraphy, magnetostratigraphy, and cyclostratigraphy, Kent et al. (1995) assigned this interval to the early Norian with an estimated numerical age range of 215–218 Ma. The Newark basin occurrences of Aetosaurus in New Jersey thus establish the entire temporal range of Aetosaurus in the Newark Supergroup, and were used by Huber et al. (1993b) and Lucas and Huber (1993) to help define the Neshanician land-vertebrate faunachron (lvf), of early–mid Norian age.

The North Carolina specimen was described briefly in an abstract by Parker (1966). Its provenance is the Triangle Brick Quarry, near Glenlee, North Carolina, which exposes a 20 m thick section of fine-medium-grained arkosic and quartzose sandstone, siltstone and shale, mapped and informally named by Hoffman and Gallagher (1989) as 'Lithofacies Association II' of the Durham sub-basin of the Deep River basin, a unit that is the stratigraphical equivalent of the lower Sanford Formation in the adjacent Sanford sub-basin (Huber et al. 1993a). Other fossils from the Triangle Brick Quarry include megafossil plants (Equisetum stem fragments), darwinulid ostracodes,
abundant conchostracans, unionid bivalves, articulated crayfish, insects, bony fishes (Synornichthys, Cionichthys, Turseodus, Semionotus, Osteplurus), hybodontid elasmobranchs, several types of vertebrate coprolites, indeterminate labyrinthodont and phytosaur teeth and bone scrap, sphenosuchian and proterosuchian crocodylomorphs, and several, recently collected partial skeletons of a new rauisuchian currently under study by P. E. Olsen (pers. comm. 1995). Based on lithostratigraphical correlation of the Durham and Sanford sub-basin successions (Olsen et al. 1990), Lithofacies Association II is stratigraphically higher than the Cumnock Formation, which produced a tetrapod fauna of latest Carnian (late Tovalian) age (Sanfordian lfv of the Newark Supergroup) (Huber et al. 1993a, 1993b). Hence, the Triangle Brick Quarry Aetosaurus comes from strata of early Norian age that belong to the early part of the Neshanican lfv, as defined by Huber et al. (1993b) and Lucas and Huber (1993).

BIOSTRATIGRAPHY AND BIOCHRONOLOGY

Tetrapod fossils provide one of the principal bases for the correlation of non-marine Triassic strata across Pangaea (Ochev and Shishkin 1989; Lucas 1990). During the Late Triassic, archosauromorph reptiles dominated tetrapod faunas. Two archosauromorph groups—phytosaurs (Parasuchidae) and aetosaurs (Stagonolepididae)—were broadly distributed across Pangaea, and their fossils are abundant in Late Triassic non-marine strata.

Phytosaurs have long been used for correlation of these strata (e.g. Camp 1930; Gregory 1957; Westphal 1976; Bullew 1989). However, they are not ideal index fossils because: (1) nearly an entire phytosaur skull is needed to make a genus- or species-level identification, whereas the vast majority of phytosaur fossils are isolated bones and skull fragments; and (2) phytosaur taxonomy is not well agreed on and generally oversplit, with three different taxonomic schemes (Bullew 1989; Hunt 1994; Long and Murry 1995).

An ideal index fossil should be widely distributed geographically, abundant, have a short temporal range, and be easily identifiable. Aetosaurs meet these four criteria:

1. Aetosaur fossils are found throughout most of Late Triassic Pangaea (Text-fig. 1). Indeed, they have a broader distribution than phytosaurs, most notably being known from Argentina, where phytosaurs have not been found (Lucas and Heckert 1996).
2. Aetosaurs are the most abundant tetrapod fossils in the Chinle Group (western USA) and the Ischigualasto Formation of Argentina (Lucas 1993; Rogers et al. 1993). They are common in many other Late Triassic deposits.
3. Stratigraphical/temporal ranges of aetosaur genera are usually relatively short—much less than a stage/age (Lucas and Heckert 1996) (Text-fig. 5).
4. Aetosaurs are easy to identify because their body armour is highly distinctive at the genus level (e.g. Long and Ballew 1985; Long and Murry 1995; Heckert et al. 1996; Lucas and Heckert 1996). A single piece or fragment of aetosaur armour, sometimes even as small as a postage stamp, can be precisely identified.

Recognition that Stegomus = Aetosaurus extends the record of this biostratigraphically significant taxon into the eastern United States. Here, we review the temporal distribution of Aetosaurus to establish its status as a non-marine index fossil of early–mid Norian time (Text-fig. 6).

Western United States

Hunt (1994) documented aetosaur scutes from the Bull Canyon Formation of the Chinle Group in east-central New Mexico. The holotype of a new genus he proposed, but did not publish, NMMNH P-17213, is a left dorsal paramedian scute, 75 mm wide and 31 mm long, so it has a low
width:length ratio of 2:4. The scute is slightly arched transversely, indicating that it is probably a caudal dorsal paramedian. The ornamentation consists of a very faint, radial pattern of elongate pits. It thus closely resembles the Newark specimens of *Aetosaurus arcaurus* reviewed here, and we assign it to that taxon. Another referred specimen from east-central New Mexico is NMMNH P-17615, a dorsal paramedian scute, 76 mm wide and 27 mm long, yielding a width:length ratio of 2.8. Associated scutes and possible material from the axial and the appendicular skeleton of these specimens will be described separately. The Bull Canyon Formation is considered to be of early–mid Norian age, based largely on the occurrence of the phytosaur *Pseudopatagus* and the aetosaur *Typothorax*, both of which are index taxa of the Revueltian lvI of Lucas and Hunt (1993).

**Greenland**

In Greenland, *Aetosaurus ferratus* occurs in the Ørsted Dal Member of the Fleming Fjord Formation (Jenkins *et al.* 1994). The Ørsted Dal Member has yielded a diverse assemblage of vertebrates: the plagiosaurid *Gerrothorax* cf. *pulcherrimus* Fraas, the cycloosaur *Cyclostosaurus* cf. *posthumus* Fraas, the turtle cf. *Proganochelys*, the aetosaurs *Aetosaurus ferratus* Fraas and *Paratyphothorax andressi* Long and Ballew, the prosauropod dinosaur *Plateosaurus engelhardti* Meyer, a theropod dinosaur, the mammals *Kuehneotherium* sp. and cf. *Brachydontodon?,* a pterosaur, coelacanth fishes, *Saurichthys?,* a lungfish, unidentified sphenodonts and lepidosaurs? and theropod dinosaur footprints (*Grallator* sp.) (Jenkins *et al.* 1994).
As Jenkins et al. (1994) concluded, this assemblage shares many taxa with the German Stubensandstein and clearly is of Norian age. The closest similarity to the Ørsted Dal assemblage is the vertebrate assemblage of the Lower Stubensandstein, especially the co-occurrence in both units of *Aetosaurus ferratus* and *Paratyphotherax andreasii*, as well as *Cyclotusaurus*, *Gerrothorax* and *Progonochelys*. We thus regard the Ørsted Dal Member vertebrates as of early Norian age (Text-fig. 6). However, we note that Jenkins et al. (1994) presented no precise stratigraphical ordering of vertebrate fossil localities in the 150–200-m thick Ørsted Dal Member and that some taxa from the Ørsted Dal Member (*Gerrothorax, Plateosaurus*) do not occur in the Lower Stubensandstein, but first appear in the Middle Stubensandstein (Benton 1993, table 1). Therefore, the possibility exists that the Ørsted Dal vertebrate assemblage includes temporal equivalents of both the Lower and Middle Stubensandstein.

**Germany**

In Germany, *Aetosaurus* is well documented from the Lower Stubensandstein (*A. ferratus*) and the Middle Stubensandstein (*A. crassicauda*) of the German Keuper (O. Fraas 1877; E. Fraas 1907; Wild 1989). Palynostratigraphy, vertebrate biostratigraphy, and sequence stratigraphy suggest that
the Stubensandstein is of early to mid Norian age (Brenner 1973; Brenner and Villinger 1981; Visscher and Brugman 1981; Benton 1986, 1993; Wild 1989; Aigner and Bachman 1992; Kozur 1993; Lucas and Huber 1994). The most precise correlation available suggests that the Lower Stubensandstein is early Norian, whereas the Middle Stubensandstein is mid Norian (e.g. Benton 1993). This suggests that *Aetosaurus* in Germany has an early–mid Norian temporal range comparable to its temporal range in the Newark Supergroup (Text-fig. 6).

**Italy**

Wild (1989) documented *Aetosaurus ferratus* from the marine Calcare di Zorzino Formation (= Zorzino Limestone) at Cene, near Bergamo in the Lombardian Alps of northern Italy. The Calcare di Zorzino Formation is a carbonate and turbidite facies that immediately overlies and is in part laterally equivalent to the Norian Dolomia Principale (= Haupt dolomit). After the regional progradation of platform carbonates (Dolomia Principale) during the early–mid Norian, extensional tectonism produced intraplatform depressions in which the Zorzino Limestone (Aralalta Group; Jadoul 1985) was deposited as patch reefs, turbiditic debris flows and lagoonal to freshwater facies (Jadoul et al. 1994). Palynostratigraphy and conodont biostratigraphy indicate that the fossil vertebrate locality in the Zorzino Limestone near Bergamo is very close to the Alunian (mid Norian)–Sevatian (late Norian) boundary (Jadoul et al. 1994; Roghi et al. 1995; Tintori and Lombardo 1996). This indicates that the *Aetosaurus* occurrence documented by Wild (1989) is of late mid Norian age, and correlates with the younger part of the *Himavaites columbi anus* Zone of the global Triassic ammonite biochronology (Tozer 1994). This provides a direct cross-correlation of an *Aetosaurus* occurrence to marine Triassic biochronology (Text-fig. 6).

**Discussion**

The direct cross-correlation of *Aetosaurus* from Italy to the middle Norian accords well with the inferred age of some *Aetosaurus* records in Germany and the United States. However, the German and American records suggest that *Aetosaurus* existed during both the early and mid Norian. Although this is consistent with cross-correlation to the Italian marine occurrence of *Aetosaurus*, the German and Newark Supergroup records obviously encompass a longer temporal range (Text-fig. 6) than the single Italian occurrence.

The total known temporal range of *Aetosaurus* thus equals about four ammonite zones, which is about half of Norian time, approximately 5–7 million years on most numerical time scales (e.g. Kent et al. 1995). *Aetosaurus* thus emerges as a tetrapod taxon capable of providing a robust correlation across much of Late Triassic Pangaea and is an index fossil of early–mid Norian time.

**Acknowledgements.** R. Barrick, P. Holroyd, D. Parris and M. A. Turner made it possible for us to study specimens of *Stegomus*. A. Tintori provided information on the age of the Zorzino Limestone, and A. Hunt provided useful discussion. The comments of two anonymous reviewers improved this article. The National Geographic Society (Grant 5412-95 to SGL) supported part of this research.
