VARIATION AND ONTOGENY OF SOME OXFORDIAN AMMONITES: TARAMELLICERAS RICHEI (DE LORIOL) AND CRENICERAS RENGERI (OPPEL), FROM WOODHAM, BUCKINGHAMSHIRE

by D. F. B. PALFRAMAN

ABSTRACT. Statistical and ontogenetic studies of Taramelllicerases richel (de Loriol) and Creniceres rengeri (Oppel) have shown identity in their early stages. Variation in protoconch size is consistent and small, as is the diameter of the nepionic constriction. Divergence in shell form occurs only at the onset of maturity, which in C. rengeri begins at about 8-4 mm. and in T. richel at about 18-8 mm. It is concluded that the two 'species' are a sexually dimorphic pair. The name C. rengeri has priority.

A COLLECTION of Lower Oxfordian ammonites was made from the Woodham Brick Company's Pit, with the objective of studying the variation and ontogeny of selected species. The pit is situated almost midway between Bicester and Aylesbury, near Ake-
man Street Station, Buckinghamshire (Grid. Ref. 707186), and exposes some seventy feet of Oxford Clay (Arkell 1939). A lithological unit 'The Lamberti Limestone', a bed one foot thick, separates the lowermost forty feet of clay (Athleta Zone) from the upper-
most thirty feet (Mariae Zone).

The Mariae Clays, as the beds of the Mariae Zone are here named, furnished the material studied. Both 'species' examined in this paper occur, together, throughout the Mariae Clays at Woodham; they are commonest in the lower ten feet of the Mariae Zone (generally pyritized), becoming rare in the upper twenty feet of beds (generally limonitized). They are both found together at all levels at Woodham. There is no evidence to suggest that either Taramelllicerases richel (de Loriol) or Creniceres rengeri (Oppel) occurs outside the Mariae Zone in this country. However, both species appear to have arisen in the Upper Lamberti Zone, being found in Haute-Saône (Maire 1908). They are both found together in the Rengeri Marls (Mariae and Cordatum Zones) of the Jura Mountains, where they are fairly common (de Loriol 1898-9, 1900 and Arkell 1939). As far as the author is aware they are not recorded above the Cordatum Zone; though, as Arkell (1939) says '... exact details of range [are] usually not available'.

All the specimens collected are preserved as internal moulds, pyritic near the base of the zone becoming limonitic towards the top. No original shell material has been found among the collection of several thousand ammonites. In a few individuals the innermost whorls are calcified, but rarely to a diameter of more than 3-4 mm. Some, which are otherwise completely pyritized or limonitized, were found to have a calcareous proto-
conch.

Very few specimens were found preserved as pyrite or limonite moulds above a maximum diameter of 2 or 3 cm. and it seems that there is a maximum size above which ammonites were not pyritized or limonitized. Internal moulds composed of clay, seen in

situ, showed that some ammonites must have had a diameter of not less than forty centimetres (see Pl. 48, fig. 1); often in the centre of such moulds were to be seen pyritized or limonitized nuclei of familiar dimensions.

Nearly five hundred specimens of Taramellliceras richei (de Loriol) and over two hundred specimens of Creniceras renggeri (Oppel) have been examined in this work. All specimens collected by, or given to, the author are in the University Museum, Oxford and are prefixed by OUM, those borrowed from the British Museum (Natural History) by BM. The following abbreviations are also used throughout the text: D = diameter, W = whorl width, HH = whorl height, U = umbilical diameter.

**VARIATION AND ONTOGENY OF TARAMELLICERAS RICHEI (DE LORIOL)**

Due to the conditions of preservation, the most frequently occurring form in which Taramellliceras richei (de Loriol) was found at Woodham, was as internal moulds of the phragmocone. The type material of T. richei is based largely on internal moulds of phragmocones (de Loriol 1896). In the author's collection of nearly five hundred specimens less than 10 per cent. have any part of the body chamber preserved, and in none of these is it complete. The species is a typical oppeid, being compressed and involute with a small umbilicus. Whorl height is approximately half the diameter, whorl width is approximately quarter the diameter. Coiling is regular in the phragmocone, but on the body chamber of adults the umbilical seam begins to uncoil.

*Protoconch*. Less than 5 per cent. of the specimens of T. richei available were found to have protoconchs preserved; in all some eight protoconchs were dissected out. These are beautifully preserved as smooth pyritic moulds, showing details of the prosutre (text-fig. 1 and Pl. 48, fig. 2a). In all cases the protoconchs are barrel-shaped with a width greater than the diameter. The largest recorded diameter of a protoconch of T. richei is 0.30 mm., the smallest 0.25 mm. (see Table 1). In one specimen (OUM J22530) the caecal mould is visible (text-fig. 1a, c).

*Phragmocone*. Just as the surface of the protoconch internal mould is smooth, so also is the first whorl of growth. The nepionic constriction occurs after one complete whorl of growth from the prosopseptum, at a diameter of about 0.55 mm., or roughly twice that of the protoconch (Table 1).

The nepionic constriction is well-defined, especially in the ventral and ventro-lateral regions, fading on the flanks and almost imperceptible near the umbilicus (text-fig. 2a, b; Pl. 48, fig. 6). In T. richei there is no ornamental difference, on the internal mould, between the whorl preceding the nepionic constriction and that immediately succeeding. In some ammonites, Kosmoceras and Garantiana, Makowski (1962) noted that the ornamentation characteristics of the full-grown shell appeared after the nepionic constriction. Ontogenetic features of note are: a decrease in the W/D ratio from the protoconch to a diameter of 0.8-1.0 mm. and a similar decrease in the U/D ratio to about the same diameter. From a diameter of 0.8-1.0 mm. onwards, growth is almost isometric until the onset of maturity which occurs at a diameter of about 18-20 mm. This is graphically represented here (text-figs. 3 and 4). From a diameter of 0.8-1.0 mm. until the onset of maturity the HH/D ratio shows almost isometric growth (text-fig. 5).
TEXT-FIG. 1. Protoconchs of Taramellliceras richel (de Loriol); Mariæ Zone, Woodham, Bucks., England. A and D, ventral view; B, inclined apertural view; C and F, apertural view; E, side view. A and C based on OUM J25230; B, D, E, and F based on OUM J25228. All × 100.

TEXT-FIG. 2. Diagram of the innermost whorls of Taramellliceras richel (de Loriol); Mariæ Zone, Woodham, Bucks., England. A, B, C, and D, drawn from OUM J25038; E, drawn from OUM J25234. All × 50.

Ribbing is completely absent until a diameter of about 4 mm.; at this diameter radial umbilical swellings begin, strongly near the umbilicus but fading on the flanks. The ribs are shallow and distant and are initially eight to ten per whorl. It is not until a diameter of about 8–10 mm. that ribbing is differentiated into primaries and intercalatories (Pl. 50, fig. 1a, c).
Differentiated ribbing is undoubtedly a characteristic of *T. riechi*, all specimens showing this feature to some degree, with a variation from relatively coarse ribbing to fine (Pl. 49, figs. 1a, b, 2a, c). On the final whorl of all adult specimens there are two series of ribs; primaries and intercalatories. The primary ribs generally number ten to twelve per whorl, developing initially as radial umbilical swellings then fading on the flanks and finally becoming relatively sharp and distinct on the ventro-lateral area. They are slightly sinuous with marked ventro-lateral prorsiradial (Pl. 48, fig. 2a; Pl. 49, figs. 1a, 2a, 4a; Pl. 50, fig. 1a). Ribs always fade on the venter of internal moulds, but may not do so on the actual surface of the shell. In some cases the venter is smooth (see Pl. 49, fig. 1b), whereas in most instances the ribbing simply becomes weaker in the ventral region (Pl. 49, fig. 2b). On the last quarter of the adult phragmocone whorl, nearly all specimens develop feeble ventral tubercles, which become stronger adorally (Pl. 49, fig. 4a, b; Pl. 50, fig. 1a, b). The tubercles coincide at the point at which opposing ribs, on either side of the venter, both primaries and intercalatories, would meet had they continued uninterrupted across the venter.

The intercalatory ribs, on the final whorl of adult specimens, generally number about forty. They are restricted to the ventro-lateral area and are identical in form with the primary ribs in this region, by way of amplitude, sharpness and direction, for each particular specimen. Between each primary rib are three to four intercalatories (Pl. 48, fig. 2a; Pl. 49, figs. 2a, 4a; Pl. 50, fig. 1a).

The mean maximum diameter of the phragmocone, of more than two hundred adult specimens, was found to be 18.8 mm., with a standard deviation (σ) of 1.51. The coefficient of variation (V = 100σ/m, where m is the mean maximum diameter, dm, of the adult phragmocones) is 8.02. The greatest diameter at which the septa are approximated was found to be 27 mm., the smallest 14 mm. (text-fig. 6). The phragmocone generally comprised 6½–7 whorls from the prosopectum. Variation in the whorl-shape is here shown diagrammatically (text-fig. 7 and Pl. 48, fig. 2a).

The sutural ontogeny of *T. riechi* develops in a way which, in Jurassic ammonites, is beginning to appear fundamental (Schindewolf 1954). The prosutural is significantly
TEXT-FIG. 3. Graphs showing the relationship between diameter and shell width of *Terevantidiscus richel* (de Loric), and of *Cretoides renggeri* (Oped). The two graphs are superimposed: the diameter axis is common, the width axis is divided into A and B scales, the B scale being one log cycle behind the A scale. Graph A (W/D for *T. richel*) is controlled by the A scale, graph B (W/D for *C. renggeri*) is controlled by the B scale. The fine dashed line on graph B is that superimposed from graph A (approximate best-fit line). The areas denoted by P (coarse dashed line) enclose measurements made on the protoconchs; M is the mean of these measurements. Encircled dots represent measurements made at the maximum diameter of complete adults; asterisks—measurements made on adult body-chambers; crosses—measurements made at the adoral end of adult phragmocones; dots—measurements made on immature phragmocones.

Inset. The same graphs plotted on a linear scale and having both axes common. a, W/D for *T. richel*; b, W/D for *C. renggeri*. The arrowed points, δ, γ and δ, δ, mark the position of the mean septate diameter of mature specimens of supposed female and male respectively. All specimens from the Mariac Zone, Woodham.
TEXT-FIG. 4. Graphs showing the relationship between diameter and umbilical diameter of *Taramelllicerat richel* (de Loriol), and of *Ctenoceras ranggeri* (Oppel). The two graphs are superimposed: the diameter axis is common, the umbilical diameter axis is divided into A and B scales, the B scale being one log cycle behind the A scale. Graph A (U/D for *T. richel*) is controlled by the A scale, graph B (U/D for *C. ranggeri*) is controlled by the B scale. The fine dashed line on graph B is that superimposed from graph A (approximate best-fit line). Conventions as for text-fig. 3.

*Inset.* The same graphs plotted on a linear scale and having both axes common. a, U/D for *T. richel*; b, U/D for *C. ranggeri*. The arrowed points, $\phi$, $\varphi$, and $\phi$, mark the position of the mean septate diameter of mature specimens of supposed female and male respectively. All specimens from the Mariee Zone, Woodham.
TEXT-FIG. 5. Graphs showing the relationship between diameter and whorl height of *Tarumelliceras richeli* (de Loriol), and of *Creticeras renggeri* (Oppel). The two graphs are superimposed: the diameter axis is common, the height axis is divided into A and B scales, the B scale being one log cycle behind the A scale. Graph A (HH/D for *T. richeli*) is controlled by the A scale, graph B (HH/D for *C. renggeri*) is controlled by the B scale. The fine dashed line on graph B is that superimposed from graph A (approximate best-fit line). Conventions as for text-fig. 3.

Inset. The same graphs plotted on a linear scale and having both axes common. *a*, HH/D for *T. richeli*; *b*, HH/D for *C. renggeri*. The arrowed points, $\delta_1$, $\delta_2$, and $\delta_3$, mark the position of the mean septate diameter of mature specimens of supposed female and male respectively. All specimens from the Marine Zone, Woodham.
different from the primary suture, having a very large ventral saddle. The primary
suture (text-figs. 1 and 8) is divided into: external (or ventral), lateral, \( U_p \), \( U_s \), and dorsal
lobes, with corresponding saddles between. These first-formed lobes have been called
'protolobes' by Schindewolf (1954): subsequent works (Schindewolf 1960, 1962, and
1963) have shown that these basic protolobes are common to all Jurassic ammonites
so far investigated. Addition of successive sutural elements in *T. richel* occurs at the

umbilical seam; this is the 'U-type' ontogeny of Schindewolf (1954). The final sutures
of adult specimens are greatly differentiated into several complex saddles and lobes
(text-fig. 8a). Sutural approximation, generally regarded as a feature of maturity, is
commonly to be seen in most specimens with a phragmocone diameter of 18–19 mm.
(Pl. 48, fig. 2a; Pl. 49, figs. 2a, 4a, 4b; Pl. 50, fig. 1a).

In the adult sutures the largest saddles are the first and second lateral and the largest
lobes the ventral and lateral. These major sutural elements show the greatest range of
variation and have been compared on either side of the venter in the same specimen, and
on the same side of the venter at similar diameters, in different specimens. Comparing
the same sutural elements, on either side of the venter for any single specimen, shows
remarkably little variation (text-fig. 9). The greatest difference recorded is in the frilling
of the most adapical accessory lobe: even so this difference is somewhat subtle and does
not compare with the wide intraspecific sutural variation shown by *Morrisceras morrissi*
(Oppe) and *Clydoniceras discus* (Sow.) mentioned by Arkell (1957).
TEXT-FIG. 7. Cross-sections through the phragmcone of *Taramellieras richei* (de Loriol). A, OUM J25041; B, OUM J25021; C, OUM J25010; D, OUM J25239; E, OUM J25241; F, OUM J25236; G, OUM J25005; H, OUM J25238. All × 4. All specimens from the Mariee Zone, Woodham.
TEXT-FIG. 8. Sutural ontogeny of *T. sichelii* (de Loricid). A, OUM J25013, × 9 (D = 15 mm); b, OUM J25036, × 15 (D = 8.7 mm); c, OUM J25036, × 18 (D = 6.4 mm); d, OUM J25036, × 20 (D = 4.6 mm); e, OUM J25036, × 25 (D = 3.13 mm); f, OUM J25036, × 30 (D = 2.13 mm); g, OUM J25036, × 35 (D = 1.53 mm); h, OUM J25036, × 50 (D = 0.85 mm); i, OUM J25040, × 50 (D = 0.32 mm). J, primary suture. All specimens from the Mariae Zone, Woodham.
TEXT-FIG. 9. Sutural variation in *Taramellina richelii* (de Loriol). a, OUM J25220 (D = 12.2 mm); b, OUM J25228 (D = 12.0 mm); c, OUM J25229 (D = 12.1 mm). All × 7. All specimens from the Mariæ Zone, Woodham.

TEXT-FIG. 10. Sutural variation in *Taramellina richelii* (de Loriol). A, OUM J25029 (D = 12 mm); b, OUM J25030 (D = 12.4 mm); c, OUM J25031 (D = 11.8 mm); d, OUM J25035 (D = 12 mm); e, OUM J25024 (D = 12 mm); f, OUM J25026 (D = 12 mm). All × 7.5. All specimens from the Mariæ Zone, Woodham.

Variation between the same sutural elements of different specimens, at approximately the same diameter, shows relatively marked differences (text-fig. 10). These differences are generally of size, however, the disposition of the elements being essentially the same. The most marked differences are between the specimens OUM J25029 and OUM

J25024 (text-fig. 10a, e). Generally speaking it seems fairly safe to say that the intraspecific sutural variation in *T. richei* is extremely small.

**Body-chamber.** The body-chamber of adult specimens of *T. richei* is quite different from the phragmocone. The most marked change is in the development of ventral and ventro-lateral spines. In some specimens spines develop quite suddenly after the last septum in both positions. Specimen OUM J25676 shows the ventral spines beginning first, the ventro-lateral spines developing later (Pl. 49, fig. 3a, b). The ventro-lateral spines are paired and alternate with those on the venter, relative to the median plane. Not all body-chambers, of specimens which are otherwise identical, become spinose: they merely retain the ventral tubercoles of the adult phragmocone (Pl. 48, fig. 5a, b). However, there is probably a whole range between tuberculate venters only, and spinose venters and ventro-lateral regions: this is supported by a collection of specimens from the Oxford Clay of Warboys, Hunts. (BM C.4333, C.10651, C.15960, C.16009, C.16010, C.19288, and C.19296), which shows precisely this range.

Ribbing on the body-chamber appears to be weaker than on the phragmocone, but the very poor preservation of the body-chambers of Woodham specimens may affect this feature. Some of the better preserved specimens from Warboys show well-defined ribs, both primaries and intercalatories, even on the flanks of the body-chamber (BM C.4333 and C.15960). The phragmocones of these specimens are otherwise identical with those from Woodham.

As would be expected in the final stages of adult specimens, the body-chamber uncoils at the umbilical seam (Pl. 49, fig. 36 and text-fig. 4). Among the Woodham specimens the author was unable to find an adult which showed the nature of the peristome. However, among three specimens from the Oxford Clay of Scarborough, Yorkshire (BM 39642, C.39588, and C.39589), labelled *Proscaphites oculatus* (Phillips), is one specimen (BM 39642) which shows the nature of the peristome (Pl. 48, fig. 7). These specimens are almost certainly conspecific with *T. richei*, developing ventral and ventro-lateral spines (Pl. 48, figs. 3 and 7); unfortunately the phragmocone is not preserved and the body-chamber of the specimens is crushed. The peristome of BM 39642 is fairly simple, its outline coinciding with the course of the primary ribs. The diameter of the almost complete specimen (45 mm.), which has a body-chamber of three-quarters of a whorl, is in agreement with the predicted size of complete adults from Woodham, assuming that the Woodham specimens have a body-chamber of about three-quarters of a whorl. If this is so, the total number of whorls from the prospekt is from 7–7½ in *T. richei*.

Among the better preserved specimens from Woodham, the phragmocone is a dull black colour, whereas that of the body-chamber is a golden reflective (if pyritic) mould. The dull black colour extends just on to the body-chamber, and in many cases a well-defined line can be traced between the black and golden parts of the body-chamber. The line is almost coincidental with the course of the primary ribs but with slightly greater ventral prorsiradiation. This line may represent the annulus (Crick 1898): however, no muscle-scars were recorded from any specimen of *T. richei* from Woodham.

**Variation and Ontogeny of Creniceras reggeri (Oppel)**

*Creniceras reggeri* is a smaller 'species' than *Taramellites richei*, complete adults rarely attaining a diameter of more than 20 mm. It appears that because of its small
size *C. renggeri* is generally to be found complete, or nearly so, as it rarely exceeds the optimum size for complete preservation as a pyritic or limonitic mould in the Oxford Clay of Woodham.

**TEXT-FIG. 11.** Cross-sections through *Creniceras renggeri* (Oppel) a, OUM J25294; b, OUM J25378; c, OUM J25378 (inner whorls of a); d, OUM J25298; e, OUM J25305; f, OUM J25322; g, OUM J25272. All except fig. c are ×4; fig. c ×30. All specimens from the Mariae Zone, Woodham.

**TABLE 2.** Measurements in millimetres of the dimensions of protoconchs and the diameter of the nepionic constriction in specimens of *Creniceras renggeri* (Oppel). All specimens from the University Museum, Oxford (OUM). All specimens from the Mariae Zone, Woodham.

Protoconch. Ontogenetically *C. renggeri* goes through identical stages as *T. richei* until the onset of maturity. Protoconchs are identical in shape to, and vary within almost the same limits as, those of *T. richei* (Table 2, cf. Table 1).

**EXPLANATION OF PLATE 49**

*Taramellliceras richei* (de Loriol). All specimens are from the Mariae Zone of Woodham, Bucks, and have been whitened with ammonium chloride. All ×3.

A-I, primary suture. All specimens from the Mariae Zone, Woodham.
Phragmocone. The nepionic constriction occurs at a diameter of between 0.53 mm. and 0.56 mm., compared with 0.52-0.56 mm. in T. richeri. However, only three measurements of the nepionic constriction were available for C. reneggeri, compared with ten for T. richeri. The whorl shape (text-fig. 11) and sutural ontogeny (text-fig. 12) of C. reneggeri vary within very similar limits to those of T. richeri (text-figs. 7 and 8).

A complete lack of ornament occurs until a diameter of about 4 mm., where shallow, distant, radial, umbilical swellings develop. These swellings fade on the flanks and do not re-form on either the venter or ventro-lateral regions. These features are consistent with those recorded in T. richeri at comparable diameters. The W/D, U/D, and HH/D ratios are identical to those of T. richeri at similar growth stages (text-figs. 3, 4, and 5).

The final whorl of the phragmocone is, in most cases, seen only on removal of the body-chamber. Septation generally ceases at a diameter of 8-9 mm. The mean diameter at which septation ceases, in over two hundred adults, is 8.4 mm.; standard deviation (σ) is 1.1; coefficient of variation (V) is 12.8 (text-fig. 6). Specimen OUM J25246, with a maximum septate diameter of 17 mm., is almost certainly a very large adult C. reneggeri (Pl. 50, fig. 5). However, variation in over two-hundred specimens of C. reneggeri is not continuous to such a large diameter, the range of continuous variation being 5-13 mm. (text-fig. 6), and it seems that the specimen in question is an extreme form.

The final whorl of the mature phragmocone is typically oppellid in character, being compressed and involute and with a narrow umbilicus. There are 4½-5½ complete whorls from the prosocum to the end of the phragmocone in adult specimens.

Radial umbilical swellings are developed, which fade on the flanks. These generally number about ten per whorl and are comparable with those in number, direction, and nature, of T. richeri at a similar diameter (Pl. 50, fig. 2a, c and cf. Pl. 50, fig. 1c). The ventro-lateral area is smooth, as is the venter, except on the final quarter whorl of adults, where feeble ventral tubercles are almost always developed. The tubercles become well-defined immediately before the beginning of the body-chamber (Pl. 50, figs. 2c, 3; Pl. 51, figs. 1a, 2a, b). Uncoiling of the umbilical seam in adults begins before the final septa are deposited (Pl. 50, figs. 2, 4, 5; and Pl. 52, figs. 2, 3, 5), becoming markedly so on the body-chamber (Pl. 50, figs. 2a, 3; Pl. 51, figs. 2a, 3; Pl. 52, figs. 1, 3, and text-fig. 13).

Sutures were drawn at a diameter of approximately 8 mm. from nine specimens, showing the first and second lateral saddles and the ventral and lateral lobes. Differences in the same suture on either side of the venter are decidedly small (text-fig. 14); whereas

D. F. B. Palframan: Some Oxfordian Ammonites

Differences between sutures of different specimens, drawn at approximately the same diameter, are more marked (text-fig. 15). The range of variation, qualitatively assessed, appears to be similar to that shown by T. richei (cf. text-figs. 9 and 10). Sutural approximation can clearly be seen in a large number of specimens (Pl. 50, figs. 2a, 3; Pl. 51, figs. 1a, 3a, 12; Pl. 52, figs. 2a, b, 3, 4, 5, 6).

Text-fig. 13. Diagrams of the umbilical seam of Cteniceras rengeri (Oppel). The positions of the last two sutures are indicated. a, position of venter and lappet indicated. A, OUM J20662; B, OUM J20673; c, OUM J25364; d, OUM J20675; e, OUM J25377. All ×10. All specimens from the Mariae Zone, Woodham.

Body-Chamber. In nearly all specimens of C. rengeri a large proportion of the final whorl is body-chamber; in complete specimens the body-chamber occupies two-thirds to three-quarters of a volute (Pl. 51, figs. 2a, 4; Pl. 52, figs. 1–3, 5, 6). In complete adult specimens the total number of whorls, counting from the prosoptum, is from 5½–6½. Morphology apart, the most striking difference between the body-chamber and phragmocone is that of colour. When pyritized the body-chamber is preserved as a golden reflective internal mould, whereas the phragmocone is a dull black colour. The body-chamber is frequently well preserved and some specimens have almost complete apertures.

Spiral striae are developed on the body-chamber of all adult specimens; this feature is particularly well seen on specimens OUM J25248, J25265 and J25392 (Pl. 51, fig. 3a; Pl. 52, figs. 2a, 6). The striation is only feebly developed on the phragmocone (Pl. 51, fig. 3a), if at all.

The ventral tubercles of the phragmocone give rise to large truncated spines on the venter of the adult body-chamber. A great deal of variation is to be seen between specimens concerning the spines. At one extreme a few specimens have perfectly smooth venters (Pl. 52, figs. 2, 4), while others develop enormous spines (Pl. 52, figs. 1, 5). Among the Woodham population, however, a complete range from smooth venters to coarsely spined ones is to be seen (Pl. 51, figs. 5–12 and Arkell 1939, pl. 9, figs. 15–27). The majority of specimens have spines similar to those of OUM J25392 (Pl. 52, fig. 6).

In complete adults there are generally nine to twelve spines on the body-chamber; however, the total number depends largely on the size of the spines: specimens with finely denticulate venters having as many as twenty-four (Pl. 51, fig. 11).
TEXT-FIG. 14. Sutural variation in Creniceras ruggeri (Oppel). A, OUM J25335 (D = 8·5 mm.); b, OUM J25327 (D = 8·0 mm.); c, OUM J25329 (D = 8·5 mm.). All ×15. All specimens from the Mariæ Zone, Woodham.

TEXT-FIG. 15. Sutural variation in Creniceras ruggeri (Oppel). A, OUM J25367 (D = 7·8 mm.); b, OUM J25366 (D = 7·6 mm.); c, OUM J25326 (D = 7·8 mm.); d, OUM J25341 (D = 8·2 mm.); e, OUM J25345 (D = 8·2 mm.); f, OUM J25355 (D = 8·1 mm.). All ×15. All specimens from the Mariæ Zone, Woodham.
The general inclination of the spines is slightly rursiradial (Pl. 51, fig. 1a; Pl. 52, fig. 6); rectiradial direction is fairly common (Pl. 51, fig. 2a) and prostriradial direction rare and, at best, very slight.

In all adult specimens which have a complete body-chamber the ventral spines fade out completely just before the aperture (Pl. 50, figs. 2a, 3, 4a; Pl. 51, figs. 2a, 4 and Pl. 52, figs. 3, 6). Spines may not develop near the aperture, or, if they do, they are formed as solid shell, a mould of which would not reflect their original shape. The first spine of OUM J20695, an incomplete adult, is truncated near the base (Pl. 51, fig. 5); obviously not broken, the spine may have formed as solid shell with only the lowermost part hollow.

On well-preserved spines, fine ridges can be seen parallel to the edge of the spine (Pl. 51, figs. 1a, d). Arising from the ventral spines in many individuals are sinuous ventro-lateral ribs, which often fade on the flanks and may, or may not, reappear weakly in the umbilical region (Pl. 51, fig. 1a). In specimens with a denticulate venter, these shallow ribs are better defined in the ventro-lateral region, weakening on the flanks and umbilical region (Pl. 51, fig. 11). Individuals with no spines rarely develop ribs; at best they are very feeble and atypically weakest in the ventro-lateral position (Pl. 52, figs. 2a, b, 4). Because of the shallowness and large width of the ribs, they are only seen in well-preserved specimens.

The peristome of adult specimens of *C. renieri* develops constrictions, flares, lappets and rostra and is considerably more ornate than that of *T. richet*. Constrictions in adults vary from feebly developed to quite strongly so (Pl. 51, fig. 2a; Pl. 50, fig. 4a). In the case of well-developed constrictions the peristome is flared (Pl. 50, fig. 4a, c); however, the conditions of preservation may have been unfavourable for faithfully recording the true shape of all lappets and rostra in this species. Lappets are generally short, close to the umbilical seam and triangular to elongate in shape (Pl. 51, figs. 2a, 4; Pl. 52, figs. 2b, 3). Flattened specimens labelled *Ammonites cristatus* Sowerby, from the Oxford Clay of Scarborough, Yorkshire, though poorly preserved, show the lappets to be considerably more elongate than shown by the Woodham specimens (Pl. 52, figs. 7, 8). The preserved part of the lappet of OUM J25325 (Pl. 51, fig. 4) is identical to the earlier part of the lappet of BM C.27545 (Pl. 52, fig. 8): the lappet of the former is obviously broken and may well have been the same shape and size as that of the latter. The two forms (*A. cristatus* and *C. renieri*) are probably conspecific, the Yorkshire individuals giving a truer outline of the lappet. In some cases the Woodham specimens have lappets which, in cross-section, are concave relative to the median plane (Pl. 50, fig. 4e; Pl. 51, fig. 2b). The rostra of Woodham specimens (Pl. 50, figs. 3, 4e; Pl. 51, figs. 2a, 4; Pl. 52, fig. 3) are almost identical with those of the Yorkshire specimens (Pl. 52, figs. 7, 8) in both size and inclination.

As on *T. richet* a line appears on the body-chamber of *C. renieri* immediately after the last septum on adult specimens, possibly representing the position of the annulus (Crick 1898). The course of this line is almost identical with that recorded for *T. richet* (Pl. 51, figs. 10, 12). Faint muscle scars were seen on the venter of several individuals: they are particularly prominent in a smooth-vented specimen, OUM J25376, where they occur immediately either side of the mid-ventral line in the earliest part of the body-chamber and extend adorally for about 50° of a volution (Pl. 52, fig. 4a, b).
DISCUSSION ON SEXUAL DIMORPHISM

De Blainville (1840) was the first author to point out the possibility of separate sexes in the ammonites. More recent work (Callomon 1955 and 1963; Makowski 1962) has shown that among synchronous large and small forms of initially identical ammonites, there is sound reason for accepting de Blainville’s claim. By analogy with living cephalopods, the large form is thought to be the female and the small form the male: these are the macroconchs (M) and microconchs (m), respectively, of Callomon (1955 and 1963).

The present author accepts the criteria of Makowski (1962) relating to sexual dimorphism in ammonites:

1. identical initial stages of ontogeny in both (large and small) forms, and identity of their phylogeny,
2. lack of intermediate forms in adult (gerontic) stages,
3. presence of both forms in the same strata,
4. numerical ratio of the supposed sexes (sex ratio), comparable to that observed in living forms.

In the foregoing account it has been shown that Tylothyris and C. renegeri agree in early ontogenetic stages but it has yet to be shown that they can be ‘phylogenetically identified’ as Callomon (1963) has pointed out; [Tylothyris and Cretaceous] both commence together at the base of the Oxfordian, basal Mainie Zone (Renegeri Marls); both are there already very variable (see Arkell 1939), and I [Callomon] have the feeling that they are merely dimorphic companions the whole of the rest of

the Upper Jurassic.' Both Taramelliceras and Cricerites extend into the Kimmeridgian
(Arkell 1957, p. L125; see Arkell, Kummel and Wright 1957; Hölder 1955 and Ziegler
1957 and 1959). As far as the author is able to determine, neither genus is found at
higher levels than the Kimmeridgian.

Among the Woodham oppelids there are certainly no intermediates between T. richel
and C. renggeri; there is a 'morphological hiatus' (Makowski 1962) of about one whorl of
growth and the largest adult C. renggeri is not as large as the smallest T. richel
(text-fig. 6). The two 'species' occupy the same strata, and, as far as can be determined,
both begin at the same level, basal Marias Zone, at Woodham.

The ratio of the large to small forms, T. richel to C. renggeri, is two to one. This can
only be an approximate ratio as specimens from Woodham with a diameter of less
than 8-9 mm. cannot reliably be differentiated into large and small forms. By analogy
with living cephalopods, which show sexual dimorphism (Sweet 1964, p. K9; Makowski
1962, pp. 56–58), it is not unreasonable to contend that the two forms, T. richel and
C. renggeri, are sexual dimorphs: they show sexual differences, both size and sex ratio,
comparable with those displayed by living cephalopods. A reconstruction of the
dimorphic pair has been produced (Pl. 52, fig. 9). It is to be inferred that the larger is
the female.

TAXONOMY

The taxonomic problems, which acceptance of the sexual dimorphism theory bring,
have been discussed at length by Callomon (1955 and 1963) and Makowski (1962).
The present author is of the opinion that sexual dimorphs of the same species should
have the same specific name (Makowski 1962), being differentiated by the zoological
symbols ϕ and ρ. The specific name accepted for a dimorphic pair should be that of the
first named 'species' (following the law of priority) and, as far as the author can assess,
there should be no more complication in ammonite taxonomy than in, say, ostracod
taxonomy where sexual dimorphs of the same species are given the same specific name.

Jéanne (1951) does not include the genus Cricerites Munier-Chalmas in the family
Taramelliceratinae Spath 1928. The genus, along with Bokowskites nov. and Poparites
Rollier, is classified by Jéanne as: 'Incertae Sedis', family Oppelidiidae Bonarelli 1894.
As the present results show, C. renggeri and T. richel are sexual dimorphs of the same
species (= C. renggeri) and on this basis the author agrees with Arkell, Kummel and
Wright's (1957) classification in which the genus Cricerites is included in the subfamily
Taramelliceratinae.

SUMMARY AND CONCLUSIONS

Cricerites renggeri (Oppel) and Taramelliceras richel (de Loriol) from Woodham
are identical in every feature up to a diameter of about 8 mm. In the late stages of the
adult phragmocone, both 'species' develop feeble ventral tubercles which become
ventral spines on the body-chamber. T. richel differs from C. renggeri in that ventro-
lateral spines may be developed on the body-chamber.

The variation shown by the sutures at diameters of 8 mm. and 12 mm., in C. renggeri
and T. richel respectively, is small and qualitatively similar. Sutural ontogeny is identical
throughout: the sutures of T. richel become more complex in the adult stages, but always
at larger diameters than are recorded for adult phragmocones of C. renggeri.
In adults the body-chamber of both 'species' uncoils at the umbilical seam. The peristome of *T. richet* is relatively simple; that of *C. renggeri* is ornate, developing flares, constrictions, rostra, and lappets.

Recent work has added substance to de Blainville's theory of sexual dimorphism in ammonites. By analogy with living cephalopods it seems probable that the large form is the female and the small form the male.

It is concluded that *Creniceras renggeri* (Oppel) and *Taramelliceras richet* (de Loriol) are really male and female respectively of the same species, and that the specific name of the dimorphic pair should be that of the earliest named form. It is finally considered that the inclusion of the genus *Creniceras* in the subfamily Taramelliceratinae is correct.

Acknowledgements. For advice and discussion the author is very grateful to Dr. M. R. House. The author is also indebted to Dr. J. H. Calmon for the gift of a large number of ammonites from Woodham and to Mr. J. M. Edmonds of the University Museum, Oxford, and Dr. M. K. Howarth of the British Museum (Natural History) for the loan of specimens in their care. The work has been done during the tenure of a S.R.C. research studentship.
